Read. Mark. Understand.

Your questions can live beside the page.

1. A small idea, worth pausing for

A derivative measures the local rate of change of a function.
It tells us how much the output changes when the input moves
by a very small amount. The value depends on where we look.

For example, consider the following function:

$$g(t) = 7t^3 - 5t + 2$$

At t = 2, the derivative is 79.

The derivative is $g'(t) = 21t^2 - 5$, so $g'(2) = 84 - 5$.

Try it in Leaf

Select the first sentence above, then choose Highlight.

One passage, one conversation.

2. A useful follow-up

Suppose a small change in t is 0.01. Near t = 2, the linear approximation predicts a change of about 79 x 0.01 = 0.79. This is an approximation because the derivative itself changes as we move away from the point where it was measured.

Ask: why is this an approximation?

Then ask for an example without restating the entire passage. Each marked passage keeps its own conversation. A question on this page does not replace a question on the previous page.

A little room for your own thoughts

Comments stay on this Mac. AI questions send the selected passage and current-page text when you press Send.
